ABSOLUTE LOCALIZATION OF FAST MOBILE ROBOTS
BASED ON AN ANGLE MEASUREMENT TECHNIQUE

U. D. HANEBECK and G. SCHMIDT

Abstract. This paper presents an algorithm for absolute localization of mobile robots, which are equipped with an onboard device making angular measurements on the location of known but undistinguishable landmarks. A simple linear solution for the robot position given N ≥ 3 angle measurements is derived. The associated uncertainties in both landmark positions and angle measurement are modeled as unknown but bounded in amplitude. Experiments with the set theoretic estimator demonstrate its simplicity and effectiveness in real-world applications.

Key Words. Angular measurement; Nonlinear filtering; Recursive Estimation; Set theory; Vehicles

1. INTRODUCTION

This paper introduces an approach for estimating the absolute posture (position z, y; orientation ψ) of a fast mobile robot on a planar surface. The algorithm processes onboard measurements of angular locations of known landmarks. Both, initialization of the robot posture and recursive in-motion posture estimation is considered.

For initialization purposes, a set of angles measured with respect to the robot coordinate system needs to be paired with a subset of the indistinguishable landmarks. In (Wiklund et al., 1988), an enumerative scheme has been reported for pairing the first three angles with landmarks. The remaining angles are used for plausibility tests. Several solutions for calculating the posture given the correct association of measured angles with landmarks have been reported. Sutherland and Thompson (1994), Tsumura et al. (1993), and Wiklund et al. (1988) consider only triples of landmarks. For the case of more than three landmarks some authors average triple solutions, others use iterative techniques. Betke and Gurvits (1994) supply a closed-form solution for N angles, which does not consider uncertainties. In this paper, a more efficient association algorithm is proposed for the fusion of every measured angle with a posture prediction that is obtained by propagating the previous estimate by means of dead-reckoning data. In this paper, a set theoretic modeling of the predominantly arising non-random uncertainties is presented. A recursive set theoretic estimator is proposed for the fusion of every measured angle with a posture prediction that is obtained by propagating the previous estimate by means of dead-reckoning data. Sect. 4 suggests an implementation with real-time capabilities. Experiments demonstrate the benefits of the developed localization algorithm in Sect. 5.

2. PROBLEM FORMULATION

Consider a pool of M indistinguishable landmarks in a two-dimensional world or map. The positions of the landmarks $x_i^M, y_i^M, i = 0, 1, \ldots, M-1$ in a reference coordinate system are assumed to be known with additive bias errors, which are of course unknown.

$$
\begin{align*}
\dot{x}_i^M &= \tilde{x}_i^M + \Delta x_i^M \\
\dot{y}_i^M &= \tilde{y}_i^M + \Delta y_i^M
\end{align*}
$$

(1)

True values of * will be denoted as \( \hat{\star} \), nominal or estimated values as \( \tilde{\star} \). The errors of every landmark are assumed to be confined to an ellipsoidal
set given by
\[
\begin{pmatrix}
\Delta z_i^{LM} \\
\Delta y_i^{LM}
\end{pmatrix}^T (C_i^{LM})^{-1} \begin{pmatrix}
\Delta z_i^{LM} \\
\Delta y_i^{LM}
\end{pmatrix} \leq 1. \tag{2}
\]
Possible correlation of errors for different landmarks is ignored. The robot is capable of determining the angular locations of these landmarks with respect to its coordinate system. Individual landmarks do not necessarily have to be distinguished. The angle measurements are corrupted by additive noise, i.e., \( \hat{\alpha} = \alpha + \Delta \alpha \), where \( \Delta \alpha \) is assumed to be bounded in amplitude according to \( |\Delta \alpha| < \delta \). To account for possible occlusion of landmarks in non-convex rooms, partitioning walls are added to the map. The landmarks are ordered in the map so that the robot detects the subset of unoccluded landmarks in that order when scanning counterclockwise.

3. DETERMINING THE INITIAL POSTURE

This section is concerned with (re-) initializing the robot posture \( z = (x, y, \psi)^T \) when only very little prior knowledge is available. A priori information is specified by confining the posture to an ellipsoidal set \( \Omega_{\alpha} \). \( M \) landmarks are available and \( 3 < N < M \) angles \( \alpha_i, i = 0, 1, \ldots, N - 1 \) have been measured. The association, i.e., the list of pairings of measured angles to landmarks is initially unknown. Inspired by the interpretation-tree (IT) method in (Drumheller, 1987), the association search is kept from becoming intractable by approaching it in two steps: In the first step, for every measured angle \( \alpha_i \), the set of visible landmarks from \( \Omega_{\alpha_i} \) is determined. In the second step, these visibility constraints are exploited for pruning the IT. Thus, only a small portion of all associations needs to be generated and tested.

Step 1: The projection of \( \Omega_{\alpha_i} \) onto the \( z/y \)-plane is examined at polar grid points \( z(r, \theta), y(r, \theta) \) for some \( r, \theta \). We define a visibility matrix \( \psi \) with dimensions \( N \times M \). The elements \( \psi_{ij} \) are boolean variables which are TRUE, if the single measured angle \( \alpha_i \) may be caused by landmark \( j \). A visibility test is performed for every grid point \( z(r, \theta), y(r, \theta) \). If the landmark \( j \) is visible, i.e., when the straight line from the considered grid point \( z(r, \theta), y(r, \theta) \) to \( y_j, z_j \) does not intersect any partitioning walls, a hypothetical angle \( \alpha_{\text{app}} \) is calculated. The minimum and maximum angles at \( z(r, \theta), y(r, \theta) \) within \( \Omega_{\alpha_i} \) are denoted as \( \psi_{\text{LOW}}, \psi_{\text{HIGH}} \) respectively. \( \alpha_i \) may then be caused by landmark \( j \), if \( \alpha_i + \psi_{\text{LOW}} < \alpha_{\text{app}} < \alpha_i + \psi_{\text{HIGH}} \).

Step 2: Only those candidate associations are generated that do not violate the visibility constraints represented by \( \psi \) and that also follow the ordering assumption. Erroneous measurements are handled efficiently by adopting the "least bad data" constraint proposed in (Grimson and Lozano-Perez, 1985). For a specific association, a tentative position \( x_T, y_T \) is calculated and checked for compatibility with the error bounds, the posture constraint \( \Omega_{\alpha_i} \), and the requirements for joint visibility of all landmarks involved.

Tentative postures are quickly calculated by use of a closed-form solution. The corresponding set of \( N - 1 \) linear equations for the position is derived next. Define \( \gamma_i \) as the difference between two consecutive angles \( \alpha_i \) and \( \alpha_{i+1} \), i.e., \( \gamma_i = \alpha_{i+1} - \alpha_i \) or
\[
\gamma_i = \arctan(\frac{x_i^{LM} + x_{i+1}^{LM}}{y_i^{LM} + y_{i+1}^{LM}} - y) - \arctan(\frac{x_i^{LM} + x_{i+1}^{LM}}{y_i^{LM} + y_{i+1}^{LM}} - x) \tag{3}
\]
Application of trigonometric identities leads to
\[
\tan(\gamma_i) = \frac{x_i^{LM} + x_{i+1}^{LM}}{1 + \frac{y_i^{LM} + y_{i+1}^{LM}}{z_i^{LM} + z_{i+1}^{LM}}}, \tag{4}
\]
which may be rewritten as
\[
y_{i+1}^{LM} + x_{i+1}^{LM} = x_i^{LM} + \cot(\gamma_i)(y_i^{LM} + y_{i+1}^{LM} - y) + z_i^{LM} + z_{i+1}^{LM} \tag{5}
\]
for \( i = 0, 1, \ldots, N - 1 \). Index operations are performed modulo \( N \), i.e., \( i + 1 = 0 \) for \( i = N - 1 \). Subtracting from every equation its follower equation yields a system of \( N - 1 \) equations that are linear in \( x \) and \( y \). The solution yields a system of \( N - 1 \) equations that are linear in \( x \) and \( y \). The solution is calculated and checked in \( z \) and \( y \). The corresponding elements are given by
\[
z_i = y_{i+1}^{LM} + \cot(\gamma_i)(y_i^{LM} + y_{i+1}^{LM} - y) + z_i^{LM} + z_{i+1}^{LM} \tag{6}
\]
and
\[
h_i = \cot(\gamma_i)(y_i^{LM} + y_{i+1}^{LM} - y) - \cot(\gamma_{i+1})(y_{i+1}^{LM} + y_i^{LM} - y) - z_i^{LM} + z_{i+1}^{LM} \tag{7}
\]
Once \( x, y \) are known, \( \psi \) can be obtained immediately. To enhance the quality of the solution, an error propagation analysis is performed, which is outside the scope of this paper.
4. IN-MOTION LOCALIZATION

The robot is assumed to be equipped with an odometry which mainly suffers from amplitudebounded noise sources, that may be strongly correlated or even deterministic. A dead-reckoning system calculates sets of relative posture compatible with the a priori given error bounds. Recursive set theoretic estimation is performed by combining information from an angle measurement at time \( k \) with a propagated version of the previous posture estimate at time \( k - 1 \). Ellipsoidal bounding sets (EBS) are used for all operations to achieve real-time capabilities.

4.1. Propagation

The result of the fusion process at time \( k - 1 \) is represented by the EBS

\[
\Omega_k^{E-1} = \{ \hat{x}_k^E : (\hat{x}_k^E - \hat{x}_k^{E-1})^T \left( C_k^{E-1} \right)^{-1} (\hat{x}_k^E - \hat{x}_k^{E-1}) \leq 1 \}.
\]

The exact set of absolute postures predicted by the dead-reckoning system is then given by

\[
\Omega_k^{E-1} = \{ \hat{x}_k^E : \hat{x}_k^E = \hat{x}_k^{E-1} + \hat{B}_k \hat{z}_k^E \},
\]

with \( \hat{x}_k^{E-1} \in \Omega_k^{E-1}, \hat{x}_k^E \in \Omega_k^A \), the identity matrix, and

\[
B_k = \begin{pmatrix}
\cos(\psi_k^{E-1}) & -\sin(\psi_k^{E-1}) \\
\sin(\psi_k^{E-1}) & \cos(\psi_k^{E-1}) \\
0 & 0
\end{pmatrix}.
\]

Unfortunately, \( \Omega_k^E \) is not in general an ellipsoid. Linearizing (9) around the nominal values yields

\[
\hat{x}_k^E - \hat{x}_k^F \approx J_k^E (\hat{x}_k^E - \hat{x}_k^F) + \hat{B}_k (\hat{x}_k^E - \hat{x}_k^F)
\]

with the Jacobian

\[
J_k^E = \begin{pmatrix}
1 & 0 & -\left( \hat{y}_k^E - \hat{y}_k^{E-1} \right) \\
0 & 1 & \left( \hat{y}_k^E - \hat{y}_k^{E-1} \right) \\
0 & 1 & 1
\end{pmatrix}.
\]

\( \Omega_k^E \) may then be approximated as the EBS for the Minkowski sum of the two ellipsoids in (11)

\[
\Omega_k^P \approx \{ \hat{x}_k^F : (\hat{x}_k^F - \hat{x}_k^P)^T \left( C_k^P \right)^{-1} (\hat{x}_k^F - \hat{x}_k^P) \leq 1 \},
\]

with center \( \hat{z}_k^P \) and \( C_k^P \) given by

\[
\hat{z}_k^P = I \hat{z}_k^{E-1} + \hat{B}_k \hat{z}_k^\Delta, \quad C_k^P = \frac{\mathbf{E}_k}{1 - \kappa} + \frac{\Gamma_k}{\kappa},
\]

with \( \mathbf{E}_k = J_k^E C_k^{E-1} (J_k^{E-1})^T \), \( \Gamma_k = \hat{B}_k C_k^E \hat{B}_k^T \), for \( 0 < \kappa < 1 \) (Schweppe, 1973). \( \kappa \) may be selected such that a measure of the "size" of \( \Omega_k^P \) is minimized. An appropriate "size" measure is the volume of \( \Omega_k^P \), which is proportional to \( \sqrt{\det(C_k^P)} \). Minimizing the volume in three dimensions leads to the problem of determining the unique root of a fourth-order polynomial in \([0, 1]\). The trace measure \( \text{tr}(C_k^P) \), i.e., the sum of the main-diagonal elements of \( C_k^P \), is mathematically most convenient. It leads to the problem of determining the unique root of a second-order polynomial in \([0, 1]\) irrespective of the problem dimensionality. Unfortunately, its meaning is questionable for the problem at hand, where \( \hat{x}_k^P, \hat{y}_k^P \) and \( \psi_k^P \) differ by some orders of magnitude. A more meaningful "size" measure leading to a minimization procedure of intermediate complexity is given by the trace measure of the projection of \( \Omega_k^P \) onto the \( x\psi \)-plane multiplied by the square of half of the projection of \( \Omega_k^P \) onto the \( \psi \)-axis. This is equivalent to \( M_{C_k^PC_k^P} \) with

\[
M_{AB} = \text{tr} \left( \text{proj}_{SS}(A) \right) \text{proj}_{SS}(B),
\]

where \( \text{proj}_{SS}(C) \) is defined by eliminating those rows and columns from \( C \) that are not associated with the considered subspace \( SS \). The minimizing \( \kappa \) is given by the unique root of

\[
K_3 \kappa^3 + K_2 \kappa^2 + K_1 \kappa + K_0 = 0
\]

in \([0, 1]\) where

\[
K_3 = 2 \left[ M_{\Delta x \Delta x} + M_{\Delta \psi \Delta \psi} - M_{\Delta x \Delta \psi} - M_{\Delta \psi \Delta x} \right],
\]

\[
K_2 = 3 \left[ M_{\Delta x \Delta \psi} + M_{\Delta \psi \Delta x} - 2 M_{\Delta x \Delta x} \right],
\]

\[
K_1 = 6 M_{\Delta x \Delta \psi} - 3 M_{\Delta \psi \Delta \psi} - 2 M_{\Delta x \Delta \psi} \]

\[
K_0 = -2 M_{\Delta \psi \Delta \psi}.
\]

The proof is straightforward and consists of differentiating the "size" measure with respect to \( \kappa \) and setting the result to zero.

4.2. Measurement

The measurement equation for a single \( \alpha_k \) at time \( k \) and an associated landmark at \( z^{LM}, y^{LM} \)

\[
\sin(\alpha_k + \psi_k^{LM}) (y^{LM} - \hat{y}_k) = \cos(\alpha_k + \psi_k^{LM}) (y^{LM} - \hat{y}_k)
\]

is linearized around the predicted posture \( \hat{x}_k^P \), the measured angle \( \hat{\alpha}_k \), and the nominal landmark position \( z^{LM}, \hat{y}^{LM} \). This yields \( \hat{r}_k = \hat{D}_k^{P} \hat{x}_k^P + e_k \) with
The constants are defined as $c_l = \sin(\phi + \psi_k^E)$, $c_2 = \cos(\phi + \psi_k^E)$, and $c_3 = c_2^2 \Xi_{LM}^E - \Xi_{LM}^E$. $e_k$ can thus be bounded, i.e., $|e_k| < e_{\text{max}}$ with

$$e_{\text{max}} = \sqrt{\left(-c_k\right)^T C_l \left(-c_k\right)} + |c_k^2 \delta_a|$$

Two equivalent representations of the measurement set will be given in the following. The first consists of two boundary planes given in normalized Hesse form as

$$N_k^T \Xi_{LM}^E + t_k^2 = 0$$

with

$$N_k = -\frac{D_k}{||D_k||}, t_k^2 = \frac{r + e_{\text{max}}}{||D_k||}, t_k^2 = \frac{r - e_{\text{max}}}{||D_k||}$$

The second representation is

$$\Omega_k^M = \{ \Xi_{LM}^E : c_1^T \Xi_{LM}^E - b_k \leq 1 \}$$

They may be converted into each other via $b = 2N_k/(t_k^2 - t_k^2), b_k = -(t_k^2 + t_k^2)/(t_k^2 - t_k^2)$.

4.3. Robust Combination of Information

Conceptionally, fusion just consists of calculating the intersection of the sets $\Omega_k^E$, $\Omega_k^M$. $\Omega_k^E$ is the ellipsoidal set of predicted postures, $\Omega_k^M$ is the measurement strip. The intersection of the two sets $\Omega_k^E$, $\Omega_k^M$ is not in general again an ellipsoid. To arrive at a recursive scheme, an ellipsoid circumscribing the intersection is required. A bounding ellipsoid is given by (Sabater and Thomas, 1991)

$$\Omega_k^E = \left\{ \Xi_{LM}^E : (\Xi_{LM}^E - \bar{\Xi}_k)^T (\bar{\Xi}_k) \leq 1 \right\}$$

$$C_k^P = K_k^E C_k^E$$

$$C_k^P = \frac{C_k^A \Delta_k \Delta_k^T}{1 + \lambda G_k}$$

$$\bar{\Xi}_k = b_k - \Delta_k^T \Xi_{LM}^E$$

$$G_k = \Delta_k^T C_k^E \Delta_k$$

$$K_k = 1 + \lambda - \lambda c_k^2/(1 + \lambda G_k)$$

for all $\lambda \geq 0$. This set has the interesting property that it both contains the intersection of the measurement and the prediction set and is itself contained in their union, i.e.,

$$(\Omega_k^M \cap \Omega_k^E) \subset \Omega_k^P \subset (\Omega_k^M \cup \Omega_k^E).$$

The non-linear fusion comprises 4 cases:

- No uncertainty reduction: The actual measurement is of no help in reducing the uncertainty, Fig 1.1 a).
- Consistency: Both planes defining the measurement set intersect the ellipsoidal prediction set, Fig. 1.1 b).
- Partial consistency: Only one plane intersects the prediction set, Fig. 1.1 c).
- Inconsistency: Prediction set $\Omega_k^E$ and measurement set $\Omega_k^M$ do not share a common point, Fig. 1.1 d).

For the case of (partial) consistency of ellipsoid and strip, the volume of the bounding ellipsoid in (24) may be minimized by selecting the weight $\lambda$ as the most positive root of the quadratic equation given by (Sabater and Thomas, 1991)

$$(N - 1)G_k^2 \lambda^2 + (2N - 1 + \epsilon_k - G_k)G_k \lambda + (1 - \epsilon_k^2) - G_k = 0,$$

where $N$ is the dimension, here $N = 3$. This result is now generalized to obtain an EBS with a minimum volume projection onto an arbitrary subspace. $\lambda_{\text{OPT}}$ is the positive real root of

$$\lambda^2 (G_k - H_k) G_k L + \lambda^2 (L G_k G_k - H_k) G_k$$

$$+ \lambda (L G_k - H_k + \epsilon_k^2 \epsilon_k^2 (H_k - G_k)) L - G_k H_k - H_k + \epsilon_k^2 H_k + L (1 - \epsilon_k^2) - H_k,$$

with $L$ the subspace dimension and

$$H_k = \Delta_k^T (C_k^E)^T \text{proj}(C_k^E)^{-1} C_k^E \Delta_k^T.$$
lead to an unreasonably small estimation set \( \Omega_E^p \). Enhanced robustness is achieved by imposing a higher priority on the set of predicted states \( \Omega_E^M \) since it contains the information obtained from all the past measurements. This priority should depend on the degree of consistency of the two sets \( \Omega_E^p \) and \( \Omega_E^M \). Roughly speaking, the idea is to select the set \( \Omega_E^M \) such that it exhibits a growing tendency towards the prediction set \( \Omega_E^p \) with falling degree of consistency of the sets \( \Omega_E^p \) and \( \Omega_E^M \). Referring to Fig. 1.2, a reasonable consistency measure is given by the intersection width \( W_E \) divided by the geometric mean of the strip width \( W_M \) and the ellipsoid width \( W_P \).

\[
CM(\Omega_E^p, \Omega_E^M) = \frac{W_E}{\sqrt{W_P W_M}}, 0 \leq CM \leq 1 \tag{29}
\]

\( \lambda \) in (24) is selected from \([0, \lambda_{OPT}]\) as an appropriate function of the consistency measure. A shifted logistic function

\[
\lambda = \lambda_{OPT}/[1 + \exp(-S(CM - M))], \tag{30}
\]

is used with \( S, M \) chosen as \( S = 10, M = 0.5 \). The influence of this extension on the fusion result is demonstrated in Fig. 2 by comparing it with the common approach for four cases. For the common approach, the volume of the resulting EBS \( \Omega_E^p \) experiences large changes when the measurement set just changes slightly. Single (unmodeled) measurement outliers lead to an extremely small EBS. On the other hand, the new approach calculates \( \Omega_E^M \) by modifying \( \Omega_E^p \) depending on its consistency with \( \Omega_E^M \). Thus, single erroneous measurements have a reduced impact on the fusion result.

A schematic overview of the proposed scheme for localization during fast motion based on angle measurements is depicted in Fig. 3. The feedback of \( \hat{z}_k^L \) to the process for determination of \( \Omega_E^M \) deserves some attention. It may replace \( \hat{z}_k^L \) iteratively refine the linearization of (18). The scheme may easily be parallelized into three tasks: The fusion loop, the determination of landmarks not occluded by partitioning walls, and dead-reckoning.

5. EXPERIMENTAL VALIDATION

The effectiveness of the new approach is demonstrated by navigating a fast (2 m/sec) omnidirectional service robot (Banebeck and Schmidt, 1994) through an office environment. An onboard laser-based goniometer takes angular measurements on retro-reflecting tape strips attached to the walls as artificial landmarks. 20 horizontal 360°-scans per second are performed; absolute accuracy is about 0.02°. Thus, the predominant uncertainties result from inaccurate knowledge about the positions of the fixed landmarks. A map contains nominal positions of 22 identical landmarks and partitioning walls, Fig. 4. The full scale robot is equipped with three independently steerable drive wheels. Dead-reckoning based on these wheels suffers from error sources like imperfect wheel coordination and uncertain wheel/floor contact points. The usual white Gaussian noise model is not appropriate here. The amplitude-bounded nature of the correlated error sources suggests the proposed set theoretic treatment. Once initialized with the algorithm introduced in Sec. 3, the robot performs 10 cycles of a predefined course, Fig. 4. The localization estimate based on the fusion of goniometer data and dead-reckoning is compared with data from dead-reckoning only. The highly correlated nature of the accumulating dead-reckoning errors is obvious. On the other hand, the vehicle is kept very accurately on track with the localization estimate. Absolute accuracy has found to be about ±2 cm and ±0.5°.
6. CONCLUSION

Set theoretic concepts have been applied to posture estimation of fast-moving mobile robots which perform angular measurements on the location of known but indistinguishable landmarks. In this context, four main results are presented:

1) A simple closed-form solution for the robot position given angular locations of $N$ known landmarks is derived, which consists of $N-1$ equations linear in the position.

2) Consistency measures for assessing the consistency of candidate posture sets are introduced to design set theoretic estimators which are robust to modeling errors.

3) The common minimum volume EBS algorithms for the intersection of an ellipsoid and a strip are extended to obtain the EBS with minimum volume projection onto an arbitrary subspace. Application to the localization problem allows consideration of the inherently higher precision in orientation, by selecting the EBS with minimum volume projection onto the zy-plane.

4) A scheme for approximate propagation of an ellipsoidal posture set with set valued data from an uncertain dead-reckoning system is given, which just involves finding the roots of a third-order polynomial.

The effectiveness of the proposed set theoretic estimator has been demonstrated by experiments with a fast omnidirectional service robot. The full scale robot is equipped with a laser-based goniometer which makes angular measurements on the location of tape strips attached to the wall as artificial landmarks. Navigation in an office environment revealed a high absolute accuracy of about ±2 cm and ±0.5°.

7. REFERENCES

8. APPENDIX

Proof of (27): The projection of $C_k^p$ onto a certain subspace is denoted as $\text{proj}(C_k^p)$ and may be written as

$$K_k \text{proj}(C_k^p) = -\lambda K_k \text{proj}(C_k^p A_k A_k^T C_k^p)^{-1} \frac{c_k}{1 + \lambda G_k} .$$

The volume of $\text{proj}(C_k^p)$ is proportional to

$$\text{det}(K_k I - \lambda K_k \text{proj}(C_k^p A_k A_k^T C_k^p)^{-1} C_k^p A_k A_k^T C_k^p) = \frac{c_k}{1 + \lambda G_k} .$$

where $C_k^p$ is defined as $C_k^p$ with the rows not associated with the subspace eliminated. Applying the matrix identity (Deller Jr and Luk, 1989)

$$\text{det}(c I + y z^T) = c^{L-1}(c + y z^T) ,$$

where $L$ is the subspace dimension, (32) becomes

$$K_k + M G_k - H_k \right) \frac{1 + \lambda G_k}{1 + \lambda G_k} ,$$

with $H_k$ from (28). Differentiating with respect to $\lambda$ and setting the result to zero yields (27).
